34

35 Artificial gauge fields create topological physics with extraordinary topological states
36 that forms the backbone of many anti-interference information transmission and device
37 designs [1,2]. Such artificial gauge fields, known as Berry curvature in topological
38 physics, can be understood through the Abelian (commutative) or non-Abelian (non-
39 commutative) properties of the correlation groups. Since the discovery of topological
40 physics in condensed matter systems, most topological systems have been built on
41 mimicking the interaction between electrons and U(1) gauge fields, following the
42 Abelian properties of electromagnetism. So far, great success has been achieved in
43 creating novel topological phases of matter in broader systems without intrinsic
44 electronic properties, such as cold atoms [3,4], photonic systems [5,6] and acoustic
45 systems [7–13], by constructing artificial Abelian gauge fields in lattice structures.
46 Some novel topological phases, such as the quadrupole topological insulator protected
47 by momentum-space nonsymmorphic symmetries, have been successfully realized
48 using artificial Abelian gauge fields [14]. The fanatical pursuit of such topological
49 phases and phenomena is due to the fact that besides their clear links to
50 electromagnetism, there are more practical motivations: the robustness properties of
51 topological systems are expected to revolutionize traditional devices.

52 In contrast, non-Abelian topology remains relatively underexplored, though it is
53 attracting growing attention due to its potential to significantly expand the theoretical
54 frameworks and phenomena of topological physics [15–21]. In nature, non-Abelian
55 gauge fields, mediating more complex strong and weak interactions, require more
56 internal states and non-commutative matrix-valued gauge potentials. They have been

57 artificially constructed in various experimental platforms such as cold atoms [22],
58 optics [23–25] and circuits [26–28], with the rapid progress in the design and
59 implementation of artificial gauge fields. A series of extraordinary physical phenomena
60 induced by artificial non-Abelian gauge fields, such as non-Abelian holonomies [29,30],
61 non-Abelian Aharonov-Bohm effect [26,31], non-Abelian topological order [32] and
62 Yang monopoles [33,34], have been found experimentally. However, these previously
63 realized non-Abelian gauge fields are not analogs of magnetic fields in momentum
64 space, namely Berry curvature, which lies at the heart of topological physics. Thus, they
65 cannot open non-trivial band gaps and realize a non-Abelian topological insulator.
66 Recently, theoretical schemes have been proposed to realize non-Abelian topological
67 insulators by engineering non-Abelian artificial gauge fields in lattice systems to
68 construct non-Abelian magnetic Brillouin zones [35–38]. However, the experimental
69 realization of non-Abelian topological insulators and their topological phenomena
70 remain elusive due to the need for complex matrix couplings and non-Abelian magnetic
71 Brillouin zones.

72 In this letter, we develop a scheme to create artificial SU(2) gauge fields in phononic
73 crystals, where layer degrees of freedom are employed to implement complex matrix-
74 valued couplings. We realize a non-Abelian topological insulator in a phononic crystal
75 by implementing this scheme in a non-Abelian Hofstadter model, which constructs a
76 non-Abelian magnetic Brillouin zone and open nontrivial topological gaps. We
77 experimentally observed a pair of boundary states with opposite spins in the narrow
78 topological gap, induced by an artificial SU(2) gauge field in momentum space. We
79 further characterized their properties, including spin rotation and flipping along a
80 specific plane of the Bloch sphere, which bear the unique signature of the non-Abelian
81 gauge field.

82 **Tight-binding model for acoustic non-Abelian topological insulator**

83 Two key elements are required for us to realize a non-Abelian topological insulator:
84 artificial SU(2) lattice gauge fields and analogs of non-Abelian magnetic fields that

85 induce non-trivial energy gaps. Starting with the tight-binding model, we present a
86 scheme to equivalently create complex matrix couplings corresponding to the elements
87 of the SU(2) matrix group, as shown in Fig. 1(a). We introduce layer degrees of freedom
88 as the pseudospin denoted by \uparrow, \downarrow . The other two pseudospin copies (lowercase and
89 uppercase letters) are used to construct equivalent conjugate imaginary couplings. In
90 the basis $(a_\uparrow, a_\downarrow, A_\uparrow, A_\downarrow, b_\uparrow, b_\downarrow, B_\uparrow, B_\downarrow)^T$, the link variables U_μ ($\mu = x, y, z$), consist of
91 purely real couplings, intralayer couplings t_0 and interlayer couplings $t_{1,2,3}$ (positive
92 in red, negative in blue), as shown in the upper panel of Fig. 1(a). By applying a unitary
93 transformation $S = \frac{1}{\sqrt{2}} \begin{pmatrix} I_2 \otimes [1, i] \otimes I_2 \\ I_2 \otimes [1, -i] \otimes I_2 \end{pmatrix}$, the basis is converted to a new one
94 $(|+i\rangle, |-i\rangle)^T$, which spans two decoupled conjugate subspaces,
95 $|+i\rangle = (a_\uparrow + iA_\uparrow, a_\downarrow + iA_\downarrow, b_\uparrow + iB_\uparrow, b_\downarrow + iB_\downarrow) / \sqrt{2}$ and $|-i\rangle = |+i\rangle^*$, as shown in the lower
96 panel of Fig. 1(a). Each subspace provides link variables V_μ between adjacent lattice
97 sites, where $V_x(\omega) = e^{-i\omega\sigma_x}$, $V_y(\theta) = e^{-i\theta\sigma_y}$, $V_z(\phi) = e^{-i\phi\sigma_z}$ are the elements of SU(2) matrix
98 group. $\omega = \arctan(t_1/t_0)$, $\theta = \arctan(t_2/t_0)$ and $\phi = \arctan(t_3/t_0)$ correspond to half
99 of the rotation angle of the Bloch sphere along the σ_x , σ_y , σ_z axes, respectively. By
100 tuning the ratios $t_{1,2,3}/t_0$, arbitrary artificial SU(2) gauge fields can be achieved.

101 We select two types of the matrix couplings U_y and U_z to construct non-Abelian
102 magnetic field analogs in non-Abelian Hofstadter models. The tight-binding model in
103 Fig. 1(b) yields the Hamiltonian:

$$104 \quad H(\theta, \phi) = - \sum_{m,n} t_x a_{m+1,n}^\dagger U_y(n\theta) a_{m,n} + t_y a_{m,n+1}^\dagger U_z(-m\phi) a_{m,n} + \text{H.c.}, \quad (1)$$

105 where $a_{m,n} = [a_{m,n,\uparrow}, a_{m,n,\downarrow}, A_{m,n,\uparrow}, A_{m,n,\downarrow}]^T$ is the annihilation operator at the (m, n) site.

106 t_x (t_y) represents the hopping amplitude along the x (y) direction, which is set to

107 $t_x = t_y = -1$ unless otherwise noted. Through a similar unitary transformation, we derive
 108 the non-Abelian Hofstadter model with link variables V_y and V_z in $|+i\rangle$ subspace, as
 109 shown in Fig. 1(c). This model describes two-dimensional spin-1/2 particles on a square
 110 lattice under an artificial SU(2) ‘magnetic field’. Hamiltonian details are provided in
 111 Supplemental Material Sec. I [42].

112 To investigate the properties of this non-Abelian Hofstadter model, we only need to
 113 consider the Hamiltonian in $|+i\rangle$ subspace, which reads:

$$114 \quad h(\theta, \phi) = -\sum_{m,n} t_x a_{m+1,n}^\dagger V_y(n\theta) a_{m,n} + t_y a_{m,n+1}^\dagger V_z(-m\phi) a_{m,n} + \text{H.c.}, \quad (2)$$

115 $V_y(n\theta) = e^{-in\theta\sigma_y}$ and $V_z(-m\phi) = e^{im\phi\sigma_z}$ represent gradient-varying link variables
 116 applied in x and y directions, respectively. The link variable $V_z(-m\phi)$, acting as the
 117 intrinsic spin-orbit coupling, provides opposite fluxes $\pm\phi$ for each spin sector.
 118 Whereas, $V_y(n\theta)$ resembles Rashba-type spin-orbit coupling, which mixes the spin
 119 components. Two types of link variables conspire to yield the artificial SU(2) gauge
 120 field, with gauge potential given as $\mathcal{A} = (-n\theta\sigma_y, m\phi\sigma_z, 0)$. Here, $\theta = 2\pi p_\theta/q_\theta$ and
 121 $\phi = 2\pi p_\phi/q_\phi$ are effective flux penetrating the unit cell normal to x and y directions,
 122 respectively, with integers $p_\theta, q_\theta, p_\phi, q_\phi$. The model in Fig. 1(c) adopts a $q_\phi \times q_\theta$
 123 magnetic unit cell and its magnetic Brillouin zone is defined as $k_x \in [0, 2\pi/q_\phi)$,
 124 $k_y \in [0, 2\pi/q_\theta)$. Two non-commuting link variables jointly drive the artificial gauge
 125 field into the non-Abelian regime for most parameters (θ, ϕ) . However, it reduces to
 126 the Abelian regime at certain specific parameter values, i.e. $\theta \in \{0, \pi\}, \phi \in \{0, \pi\}$,
 127 or $\{\theta, \phi\} \in \{\pi/2, 3\pi/2\}$. The relevant magnetic-field effects and their nature can be
 128 detected by the Wilson loop (see End Matter for details).

129 **Acoustic implementation for a non-Abelian topological insulator**

130 We now consider a phononic crystal implementation of a non-Abelian topological
 131 insulator induced by the artificial SU(2) gauge fields. We employ two link variables,
 132 $U_y(\pi/2)$ and $U_z(-4\pi/3)$, as examples to present the key components for constructing
 133 acoustic SU(2) gauge fields, as illustrated in Figs. 2(a) and 2(b). Each site consists of
 134 four layers of cuboid acoustic cavities (height $h_0 = 45$ mm, width $w = 10$ mm), serving
 135 as artificial atoms with an onsite frequency $f_0 = 3830$ Hz. By adjusting the position
 136 and diameter of the intralayer and interlayer tubes, the sign (positive in red, negative in
 137 blue) and strength of the couplings can be precisely controlled, respectively. For
 138 $U_y(\pi/2)$, only interlayer tubes with diameter $d_1 = 3.6$ mm exist, corresponding to a
 139 coupling strength of 106 Hz and $\theta = \pi/2$. For $U_z(-4\pi/3)$, intralayer ($d_2 = 1.9$ mm)
 140 and interlayer ($d_3 = 3.2$ mm) tubes yield the coupling strength of -53 Hz and 92 Hz,
 141 respectively, with their ratio yielding $\phi = -4\pi/3$. These acoustic link variables agree
 142 well with the tight-binding model (Supplemental Material Sec. II [42]). By fine-tuning
 143 the coupling ratio, arbitrary artificial SU(2) gauge fields can be achieved. Based on the
 144 tight-binding model, we develop the acoustic Hofstadter model, where the link
 145 variables $U_y(\theta)$ and $U_z(\phi)$ vary with gradients along the x and y directions,
 146 respectively. We take $(\theta, \phi) = (\pi, 2\pi/3)$ and $(\theta, \phi) = (\pi/2, 2\pi/3)$ for the Abelian and
 147 non-Abelian cases, as shown in Figs. 2(c) and 2(d). Their unit cell size is $ma \times na$,
 148 where m (n) is the site along the x (y) direction and $a = 32$ mm is the distance between
 149 adjacent sites. The two cases differ in the flux $\theta = \pi$ adopted in the Abelian case, where
 150 all x -direction link variables, $U_y(2\pi)$ and $U_y(\pi)$, reduce to the identity matrix and
 151 commute with y -direction link variables. Consequently, the Wilson loop (accumulated
 152 phase along a closed path) around each plaquette becomes Abelian, driving the system
 153 into the Abelian regime. In non-Abelian cases, x - and y -direction link variables remain
 154 non-commuting, keeping Wilson loop non-Abelian. The Hamiltonians and structural

155 details are provided in Supplemental Material Secs. III and IV [42], respectively.

156 Each subspace hosts a total of $m \times n \times 2$ bulk bands, which are $m \times n$ Kramers
157 partners. Since the system exhibits chiral symmetry for even $q_\theta q_\phi$, the simulated bulk
158 bands of the Abelian and non-Abelian cases symmetric around ‘zero energy’, resulting
159 in the double Dirac points (purple spheres) at ‘zero energy’ frequency, as shown in Figs.
160 2(e) and 2(f), respectively. Under an Abelian gauge field, multiple topologically
161 nontrivial band gaps emerge, corresponding to the quantum spin Hall effect (QSHE).
162 For the non-Abelian case, the SU(2) gauge field opens multiple more complex and
163 narrower band gaps, indicating a non-Abelian topological insulator with richer
164 topological properties beyond the QSHE. Such artificial non-Abelian gauge fields in
165 momentum space, known as the non-Abelian Berry curvature, induces nontrivial non-
166 Abelian topology, which is expressed as:

167
$$\mathbf{F}_{xy}^\pm = \partial_x A_y^\pm - \partial_y A_x^\pm - i[A_x^\pm, A_y^\pm]. \quad (3)$$

168 Here, $A_{mn}^\pm = i \langle \pm \phi_m(k) | \nabla_k | \pm \phi_n(k) \rangle$ is the non-Abelian Berry connection and $|\pm \phi_i\rangle$
169 represent the Bloch states below the i -th gap of the $q_\phi \times q_\theta$ unit cell. For the non-
170 Abelian case $[A_x^\pm, A_y^\pm] \neq 0$, the non-Abelian Berry curvature, which takes the same
171 form as the Yang-Mills gauge field strength [39], can be interpreted as an analog of the
172 non-Abelian magnetic field. The topological invariants, labeled in right of the bulk
173 bands, are captured by integrating the non-Abelian Berry curvature (Supplemental
174 Material Sec. V [42]). Beyond the band structure, the non-Abelian Hofstadter butterfly
175 spectrum reveals a more complex fractal structure with narrow topological gaps,
176 distinct from the Abelian counterpart (see End Matter).

177 **Non-Abelian boundary states with spin-rotation characteristics**

178 To demonstrate the topological properties of the boundary states induced by artificial
179 non-Abelian gauge fields, we 3D-printed acoustic Abelian and non-Abelian topological
180 insulator samples. Boundary states are excited by four per-layer acoustic sources at the
181 hard boundary, with amplitude and phase controlled independently via power amplifiers

182 and phase shifters. Sound pressure fields are measured by sequentially placing a
 183 subwavelength microphone into each boundary cavity, with sound signals recorded
 184 using an oscilloscope. Samples and experimental details are given in the End Matter.
 185 Figure 3 presents the measured boundary states within the lowest energy gap along the
 186 y -boundary. For the Abelian topological insulator, the measured projected band
 187 dispersions (colormaps) agree well with simulations, as shown in Fig. 3(a). The
 188 simulated helical boundary states and bulk states are denoted by dashed lines and gray
 189 regions, respectively. By projecting the boundary states extracted from experiments and
 190 simulations onto the Bloch sphere, we find that the spin of the boundary state lies along
 191 the σ_z direction of the Bloch sphere, as shown in Fig. 3(b). The Abelian topological
 192 boundary states exhibit the QSHE, in which pure spin-up and spin-down states
 193 experience opposite magnetic fluxes and propagate helically along the boundaries in
 194 opposite directions. In contrast, the non-Abelian case involves spin interactions related
 195 to the non-Abelian gauge field, yielding narrower gaps and distinct boundary state
 196 properties. The measured and simulated projected band dispersions are presented in Fig.
 197 3(c). The boundary states with given k values are projected onto the Bloch sphere, as
 198 shown in Fig. 3(d). The spin projections of non-Abelian boundary states lie on a specific
 199 plane $\sigma_y - \sigma_z$ within the Bloch sphere rather than along a certain axis as in the Abelian
 200 case. Furthermore, as k_y varies, the spin polarizations of non-Abelian helical boundary
 201 states exhibit a spin-rotation behavior near the plane $\sigma_y - \sigma_z$. Owing to time-reversal
 202 symmetry, the helical boundary states at opposite k are mutually orthogonal, marked in
 203 red and blue. The spin-rotation characteristics of the non-Abelian boundary states also
 204 remain robust against perturbations (Supplemental Material Sec. VIII [42]). The spin-
 205 rotation behavior along a specific plane arises from the chosen non-Abelian gauge
 206 potential $A = (-n\theta\sigma_y, m\phi\sigma_z, 0)$. In the symmetric gauge, adopting other Pauli matrix
 207 combinations in A shift the spin-rotation plane, while other topological features
 208 remain unchanged (Supplemental Material Sec. IX [42]). The spin-rotation angle can

209 be adjusted by modifying the boundaries (Supplemental Material Sec. X [42]). Thus,
210 beyond inheriting the helical transmission of Abelian boundary states, the non-Abelian
211 boundary states further manifest non-Abelian gauge field effects through spin
212 interactions. The measured Abelian and non-Abelian boundary states along the x
213 direction are given in the Supplemental Material Sec. XI [42].

214 **Spin flipping in non-Abelian boundary states**

215 To further verify the spin interaction under artificial non-Abelian gauge fields, we
216 experimentally investigate the spin flipping of non-Abelian boundary states through an
217 H-shaped phononic crystal with four channels. Figure 4(a) schematizes the H-shaped
218 structure, consisting of two non-Abelian topological insulator blocks connected by a
219 narrow bridge (Supplemental Material Sec. XII [42]). Channels 1-4 support y -direction
220 boundary states shown in Fig. 3(c). In a uniform periodic structure, the spin polarization
221 of non-Abelian boundary states is position-independent and does not flip along a single
222 channel. However, when the structure is bent into an H-shaped structure, the spin
223 interactions between the boundary waves propagating along the upper and lower sides
224 of the narrow bridge become activated, inducing boundary state spin flipping. Exciting
225 a boundary state projected onto the upper half of the Bloch sphere in channel 1 (green
226 star) allows transmission only to channels 2 and 3 (red arrows), while transmission to
227 channel 4 requires the state flipping to its orthogonal spin-projected counterpart (blue
228 arrow). Figure 4(b) presents the simulated transmission at 3564 Hz. Spin flipping
229 oscillates periodically with the narrow-bridge length L_m , which modulates the
230 interference phase difference between transmitted and reflected waves propagating
231 along the bridge [40,41]. For $L_m = 2a$, the simulated and experimental top-layer sound
232 field distributions are plotted in Figs. 4(c) and 4(d), respectively, confirming wave
233 transmission from channel 1 to channel 4. Sound pressure responses of each layer at
234 the four channels are measured and projected into spin space, directly revealing spin-
235 flipping behavior in Figs. 4(e) and 4(f). Sound waves with upper Bloch-sphere spin
236 projection preserve their spin in channels 2 and 3, yet flip to an orthogonal state in

237 channel 4. This spin-flipping process occurs on the plane $\sigma_y - \sigma_z$ (blue plane), arising
238 from the spin interactions induced by the non-Abelian gauge fields. Tuning the spin
239 interactions within the H-shaped waveguide enables spin manipulation and acoustic
240 beam splitting (Supplemental Material XIII [42]).

241 **Conclusion**

242 We have developed a scheme to construct artificial SU(2) gauge fields in spinless
243 system, which can realize a non-Abelian topological insulator in a phononic crystal. In
244 addition, we have experimentally observed the features of boundary states in the non-
245 Abelian topological insulator, including spin rotation and flipping along a specific plane
246 of the Bloch sphere, which exhibit the signatures of the underlying non-Abelian gauge
247 field. This work implies two fundamental aspects that differ from earlier works on
248 artificial non-Abelian gauge fields. Firstly, we propose a novel scheme for constructing
249 artificial SU(2) gauge fields in spinless systems by utilizing layer degrees of freedom.
250 Secondly, we realize and characterize a non-Abelian topological insulator induced by
251 artificial SU(2) gauge fields for the first time. This scheme provides a reliable approach
252 for exploring non-Abelian physics in classical systems. Our results are expected to
253 stimulate broad interest in expanding the theoretical frameworks and exploring the
254 phenomena of topological physics.

End Matter

417

Wilson loop ----- The magnetic-field effect of the non-Abelian Hofstadter model can
 418 be obtained by tracking the accumulated phase along a closed loop C of a square
 419 plaquette. Such phase, known as non-Abelian holonomy, is obtained by evaluating the

420

Wilson loop $W_{m,n} = \exp\left(i\oint_C A \cdot dr\right)$ counterclockwise around the plaquette, starting

421

from its lower-left corner site $\mathbf{r} = (m, n)$. From the commutation relations of the Wilson

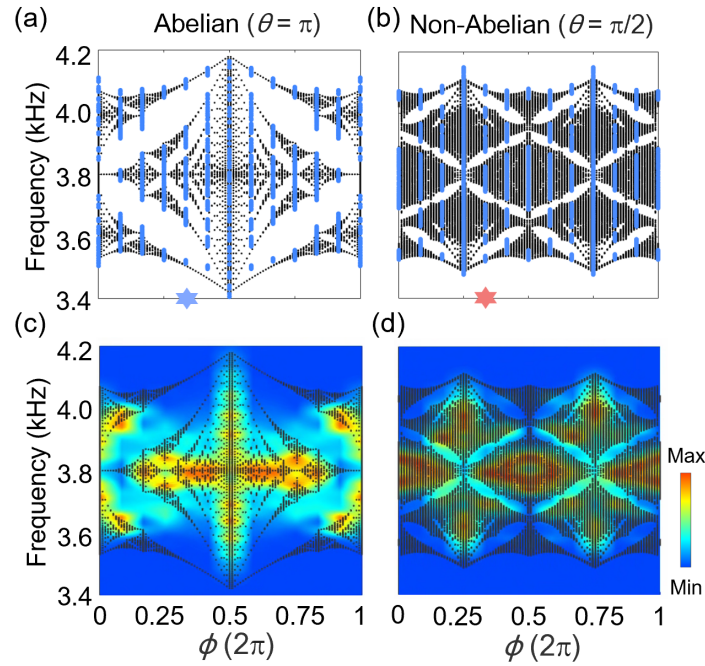

422

loops, one can identify the nature of the artificial gauge fields [3,35]. In general, the

423

Wilson loop satisfies $[W_{m,n}, W_{m',n'}] \neq 0$ for $m \neq m'$ and $n \neq n'$, which indicates a non-

424 Abelian magnetic flux in the plaquette. However, when the values of (θ, ϕ) cause
425 Wilson loop to satisfy $[\mathbf{W}_{m,n}, \mathbf{W}_{m',n'}] = 0$, the gauge field reduces to an Abelian case. Its
426 Wilson loop is $\mathbf{W}_{m,n} = \begin{pmatrix} e^{i\alpha} & 0 \\ 0 & e^{-i\alpha} \end{pmatrix}$, indicating that different spins experience opposite
427 magnetic fluxes α in the plaquette. From the commutation property of the Wilson loop,
428 we can verify the nature of the gauge field constructed by the non-Abelian Hofstadter
429 model: it remains predominantly non-Abelian for most parameter values (θ, ϕ) , but
430 reduces to an Abelian one at certain special parameter values, i.e. $\theta \in \{0, \pi\}$,
431 $\phi \in \{0, \pi\}$, or $\{\theta, \phi\} \in \{\pi/2, 3\pi/2\}$ [3,35].

432
433 **Fig. 5 Acoustic Abelian and non-Abelian Hofstadter butterflies.** (a), (b) Acoustic
434 Hofstadter butterflies as a function of ϕ for Abelian and non-Abelian cases,
435 respectively. (c), (d) The simulated acoustic transmission spectra for Abelian and non-
436 Abelian cases, respectively.

437 *Acoustic Hofstadter butterfly spectrum*-----By fixing $\theta = \pi$ and $\theta = \pi/2$, we
438 design a series of acoustic unit cells (see details in Supplemental Material Sec. VI [42]),

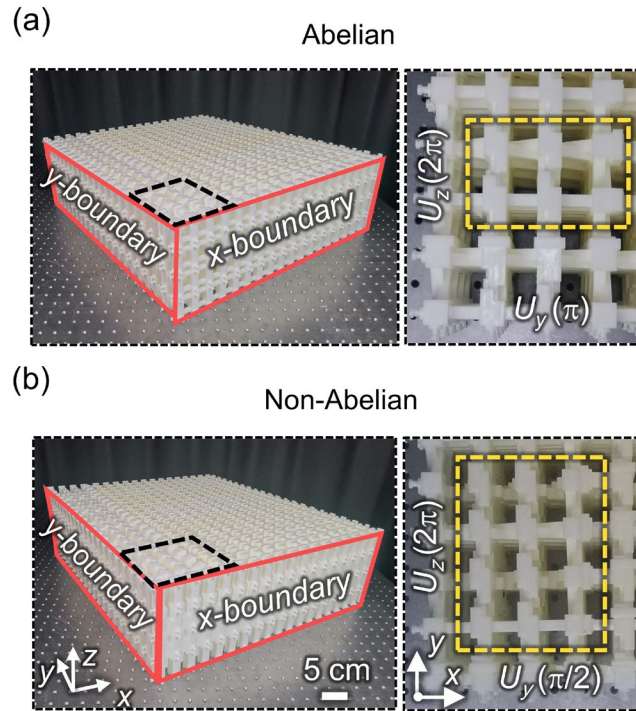

439 where flux ϕ is tuned from 0 to 2π in discrete steps of $\pi/6$ by precisely
 440 engineering the coupling strength, corresponding to the artificial Abelian and non-
 441 Abelian cases, respectively. For the Abelian case, the eigenfrequency spectrum as a
 442 function of the flux ϕ is plotted in Fig. 5(a). The black and blue dots represent the
 443 results from tight-binding model and simulations, respectively. The detailed parameters
 444 for tight-binding model are provided in Supplemental Material Sec. VII [42]. The
 445 fractal shape corresponding to the Abelian Hofstadter butterfly of QSHE, which
 446 describes spin-1/2 electrons in a uniform strong magnetic field with different strengths.
 447 Owing to the time-reversal symmetry and spin conservation, the two spin spaces
 448 decouple into two time-reversed copies of the Hofstadter butterfly. For the non-Abelian
 449 case, the butterfly spectrum exhibits more complex fractal features with a set of narrow
 450 nested gaps, as shown in Fig. 5(b). Compared with the Abelian case, the non-Abelian
 451 magnetic field exerts a significant influence on the fractal characteristics and multi-
 452 energy gap structure of the butterfly spectrum. The values of θ and ϕ corresponding
 453 to the blue and red stars are adopted in the experiments.

454 Furthermore, the transmission of the butterfly spectrum also reveals distinct
 455 differences between the two fractal structures. Finite acoustic structures with the size
 456 of $12a \times 12a$ are used to numerically simulate the transmission spectrum. Using full-
 457 wave simulations, we excite each finite acoustic structure at the bottom boundary and
 458 extract the transmitted acoustic pressure at the top boundary. We record the simulated
 459 transmission spectrum as a function of flux ϕ under different gauge fields. In the
 460 Abelian gauge fields, the simulated transmission spectra (colormaps) of the Hofstadter
 461 acoustic crystals are shown in Fig. 5(c). As expected, the transmission spectra clearly
 462 reveal the characteristic outline of the Abelian Hofstadter butterfly (black dots). In the
 463 non-Abelian gauge fields, the simulated transmission spectra reproduce a more
 464 complex nested fractal structure of the non-Abelian Hofstadter butterfly, as shown in
 465 Fig. 5(d). The simulated transmission spectra of the Hofstadter acoustic crystals are in

466 good agreement with the theoretical results, demonstrating that this design method is
 467 effective for exploring artificial non-Abelian gauge fields in spinless systems.

468 *Experiments*-----Abelian and non-Abelian acoustic samples are fabricated via 3D
 469 printing using UV resin, as shown in Figs. 6(a) and 6(b), respectively. For the Abelian
 470 topological insulator, the truncated y - and x -boundaries along the x and y directions are
 471 located at link variables $U_z(2\pi)$ and $U_y(\pi)$, respectively; for non-Abelian topological
 472 insulator, they are located at $U_z(2\pi)$ and $U_y(\pi/2)$, respectively, as represented by the
 473 red boxes. Acoustic signals are generated by a B&K network analyzer (B&K Type
 474 3160), then split into four channels, with their amplitudes independently controlled by
 475 power amplifiers and their phases independently adjusted using phase shifters. Four
 476 balanced armature speakers (Knowles WBFK30095) are placed at the hard boundary,
 477 one in each layer, as sound sources. A sub-wavelength microphone probe (B&K Type
 478 4961) is used to probe the pressure response, and the pressure signals are recorded by
 479 an oscilloscope (RIGOL HDO4204). To measure the projected band dispersions along
 480 the k_x and k_y directions, the sound sources are placed at the x - and y -boundaries of the
 481 samples depicted in Figs. 6(a) and 6(b). To probe the boundary states with $k_x > 0$
 482 ($k_x < 0$), the sound sources are placed on the left (right) sides of the x boundary in each
 483 layer. Similarly, to measure the boundary states with $k_y > 0$ ($k_y < 0$), the sound
 484 sources are placed on the lower (upper) of the y -boundary in each layer. The sound
 485 pressure field $\psi_L(m, \omega)$ at each frequency along x - or y -boundary can be obtained by
 486 measuring the sound pressure in each cavity layer by layer along the boundary, where
 487 m denotes the site of the L -th layer along the x or y direction. The sound pressure
 488 response $\varphi_{\pm}(m, \omega)$ in the subspace $|\pm i\rangle$ can be obtained through a unitary
 489 transformation $(\varphi_+(m, \omega), \varphi_-(m, \omega))^T = S_1 \psi(m, \omega)$, where $S_1 = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & i \\ 1 & -i \end{pmatrix} \otimes I_2$ and

490 $\boldsymbol{\psi}(m, \omega) = (\psi_1(m, \omega), \psi_2(m, \omega), \psi_3(m, \omega), \psi_4(m, \omega))^T$. Here, we focus on a single
491 subspace $|+i\rangle$. The projected band dispersions are obtained by applying fast Fourier
492 transformation to the sound pressure field distributions $\varphi_+(m, \omega)$, yielding the
493 momentum-space fields $\varphi_+(k_\mu, \omega)$, $\mu = x, y$. For a given wave vector k_μ , the spin
494 polarizations of the helical boundary states along the x or y directions are derived by
495 projecting them onto the Bloch sphere $\langle \sigma_\alpha \rangle = \langle \varphi_+(k_\mu, \omega) | \sigma_\alpha | \varphi_+(k_\mu, \omega) \rangle$. The acoustic
496 pressure field distributions of the H-shaped structure in Fig. 4(d) are measured by
497 placing sound sources at the position denoted as a green star in Fig. 4(a). The acoustic
498 pressure in each cavity on the top layer is then measured sequentially using the
499 microphone probe.
